Cheat Sheet: Python Data Structures Part-2

Dictionaries

Package/Method Description		Code Example	
Creating a Dictionary	A dictionary is a built-in data type that represents a collection of key-value pairs. Dictionaries are enclosed in curly braces {}.	Example: dict_name = {} #Creates an empty dictionary person = { "name": "John", "age": 30, "city": "New York"	
Accessing Values	You can access the values in a	Syntax: Value = dict_name["key_name"]	

about:blank 1/11

	dictionary using their corresponding keys.	Example: name = person["name"] age = person["age"]	
Add or modify	Inserts a new key-value pair into the dictionary. If the key already exists, the value will be updated; otherwise, a new entry is created.	<pre>Syntax: dict_name[key] = value Example: person["Country"] = "USA" # A new entry will be created. person["city"] = "Chicago" # Update the existing value.</pre>	
del	Removes the specified key-value pair from the dictionary. Raises a KeyError if	Syntax: del dict_name[key] Example: del person["Country"]	

	the key does not exist.	
update()	The update() method merges the provided dictionary into the existing dictionary, adding or updating key- value pairs.	<pre>Syntax: dict_name.update({key: value}) Example: person.update({"Profession": "Doctor"})</pre>
clear()	The clear() method empties the dictionary, removing all key-value pairs within it. After this operation, the dictionary is still	Syntax: dict_name.clear() Example: grades.clear()

	accessible and can be used further.		
You can check for the existence of a key in a dictionary using the in keyword		Example: if "name" in person: print("Name exists in the dictionary.")	
copy()	Creates a shallow copy of the dictionary. The new dictionary contains the same key-value pairs as the original, but they remain distinct	Syntax: new_dict = dict_name.copy() Example: new_person = person.copy() new_person = dict(person) # another way to create a copy	

	objects in memory.	
keys()	Retrieves all keys from the dictionary and converts them into a list. Useful for iterating or processing keys using list methods.	<pre>Syntax: keys_list = list(dict_name.keys()) Example: person_keys = list(person.keys())</pre>
values()	Extracts all values from the dictionary and converts them into a list. This list can be used for further processing or analysis.	<pre>Syntax: values_list = list(dict_name.values()) Example: person_values = list(person.values())</pre>

about:blank 5/11

items()	Retrieves all key-value pairs as tuples and converts them into a list of tuples. Each tuple consists of a key and its corresponding value.	<pre>Syntax: items_list = list(dict_name.items()) Example: info = list(person.items())</pre>
---------	--	---

Sets

Package/Method	Description	Code Example
add()	Elements can be added to a set using the 'add()' method. Duplicates are automatically removed, as sets only store unique values.	Syntax: set_name.add(element) Example: fruits.add("mango")

about:blank 6/11

clear()	The 'clear()' method removes all elements from the set, resulting in an empty set. It updates the set inplace.	<pre>Syntax: set_name.clear() Example: fruits.clear()</pre>
copy()	The 'copy()' method creates a shallow copy of the set. Any modifications to the copy won't affect the original set.	<pre>Syntax: new_set = set_name.copy() Example: new_fruits = fruits.copy()</pre>
Defining Sets	A set is an unordered collection of unique elements. Sets are enclosed in curly braces `{}`. They are useful for storing distinct values and performing set operations.	<pre>Example: empty_set = set() #Creating an Empty Set fruits = {"apple", "banana", "orange"}</pre>

about:blank 7/11

discard()	Use the 'discard()' method to remove a specific element from the set. Ignores if the element is not found.	Syntax: set_name.discard(element) Example: fruits.discard("apple")
issubset()	The 'issubset()' method checks if the current set is a subset of another set. It returns True if all elements of the current set are present in the other set, otherwise False.	<pre>Syntax: is_subset = set1.issubset(set2) Example: is_subset = fruits.issubset(colors)</pre>

about:blank 8/11

issuperset()	The 'issuperset()' method checks if the current set is a superset of another set. It returns True if all elements of the other set are present in the current set, otherwise False.	<pre>Syntax: is_superset = set1.issuperset(set2) Example: is_superset = colors.issuperset(fruits)</pre>
pop()	The 'pop()' method removes and returns an arbitrary element from the set. It raises a 'KeyError' if the set is empty. Use this method to remove elements when the order doesn't matter.	<pre>Syntax: removed_element = set_name.pop() Example: removed_fruit = fruits.pop()</pre>
remove()	Use the 'remove()' method to remove a specific element from the set. Raises a	Syntax: set_name.remove(element) Example:

	`KeyError` if the element is not found.	fruits.remove("banana")
Set Operations	Perform various operations on sets: 'union', 'intersection', 'difference', 'symmetric difference'.	<pre>Syntax: union_set = set1.union(set2) intersection_set = set1.intersection(set2) difference_set = set1.difference(set2) sym_diff_set = set1.symmetric_difference(set2) Example: combined = fruits.union(colors) common = fruits.intersection(colors) unique_to_fruits = fruits.difference(colors) sym_diff = fruits.symmetric_difference(colors)</pre>
update()	The 'update()' method adds elements from another iterable into the set. It maintains the uniqueness of elements.	<pre>Syntax: set_name.update(iterable) Example: fruits.update(["kiwi", "grape"])</pre>
